Chapter 4-(1)

Chapter 4 The tidyverse

Up to now we have been manipulating vectors by reordering and subsetting them through indexing. However, once we start more advanced analyses, the preferred unit for data storage is not the vector but the data frame. In this chapter we learn to work directly with data frames, which greatly facilitate the organization of information. We will be using data frames for the majority of this book. We will focus on a specific data format referred to as tidy and on specific collection of packages that are particularly helpful for working with tidy data referred to as the tidyverse.

We can load all the tidyverse packages at once by installing and loading the tidyverse package:

```
library(tidyverse)
## -- Attaching packages -----
                                                ----- tidyverse 1.3.1 --
## v ggplot2 3.3.5
                             0.3.4
                    v purrr
## v tibble 3.1.3
                    v dplyr
                             1.0.7
                    v stringr 1.4.0
## v tidyr
           1.1.3
## v readr
           2.0.1
                    v forcats 0.5.1
## -- Conflicts ----- tidyverse_conflicts() --
## x dplyr::filter() masks stats::filter()
## x dplyr::lag()
                  masks stats::lag()
```

We will learn how to implement the tidyverse approach throughout the book, but before delving into the details, in this chapter we introduce some of the most widely used tidyverse functionality, starting with the dplyr package for manipulating data frames and the purrr package for working with functions. Note that the tidyverse also includes a graphing package, ggplot2, which we introduce later in Chapter 7 in the Data Visualization part of the book; the readr package discussed in Chapter 5; and many others. In this chapter, we first introduce the concept of tidy data and then demonstrate how we use the tidyverse to work with data frames in this format.

4.1 Tidy data

We say that a data table is in tidy format if each row represents one observation and columns represent the different variables available for each of these observations. The murders dataset is an example of a tidy data frame.

```
library(dslabs)
data(murders)
head(murders)
```

```
state abb region population total
##
## 1
                                4779736
        Alabama
                 AL
                      South
                                           135
## 2
         Alaska
                  ΑK
                        West
                                 710231
                                            19
## 3
                                6392017
                                           232
        Arizona
                  A7.
                       West
## 4
       Arkansas
                  AR
                       South
                                2915918
                                            93
## 5 California
                  CA
                               37253956
                                          1257
                       West
## 6
       Colorado
                  CO
                        West
                                5029196
```

Each row represent a state with each of the five columns providing a different variable related to these states: name, abbreviation, region, population, and total murders.

To see how the same information can be provided in different formats, consider the following example:

This tidy dataset provides fertility rates for two countries across the years. This is a tidy dataset because each row presents one observation with the three variables being country, year, and fertility rate. However, this dataset originally came in another format and was reshaped for the dslabs package. Originally, the data was in the following format:

The same information is provided, but there are two important differences in the format: 1) each row includes several observations and 2) one of the variables, year, is stored in the header. For the tidyverse packages to be optimally used, data need to be reshaped into tidy format, which you will learn to do in the Data Wrangling part of the book. Until then, we will use example datasets that are already in tidy format.

Although not immediately obvious, as you go through the book you will start to appreciate the advantages of working in a framework in which functions use tidy formats for both inputs and outputs. You will see how this permits the data analyst to focus on more important aspects of the analysis rather than the format of the data.

4.2 Exercises

- 1. Examine the built-in datset co2. Which of the following is true:
- a. co2 is tidy data: it has one year for each row.
- b. co2 is not tidy: we need at least one column with a character vector.
- c. co2 is not tidy: it is a matrix instead of a data frame.
- d. co2 is not tidy: to be tidy we would have to wrangle it to have three columns(year, month and value), then each co2 observation would have a row.

#d

- 2. Examine the built-in dataset ChickWeight. Which of the following is true:
- a. ChickWeight is not tidy: each chick has more than one row.
- b. ChickWeight is tidy: each observation (a weight) is represented by one row. The chick from which this measurement came is one of the variables.
- c. ChickWeight is not tidy: we are missing the year column.
- d. ChickWeight is tidy: it is stored in a data frame.

#d

- 3. Examine the built-in dataset BOD. Which of the following is true:
- a. BOD is not tidy: it only has six rows.

- b. BOD is not tidy: the first column is just an index.
- c. BOD is tidy: each row is an observation with two values (time and demand)
- d. BOD is tidy: all small datasets are tidy by definition.

#c

- 4. Which of the following built-in datasets is tidy (you can pick more than one):
- a. BJsales
- b. EuStockMarkets
- c. DNase
- d. Formaldehyde
- e. Orange
- f. UCBAdmissions

#c,d,e

4.3 Manipulating data frames

The dplyr package from the tidyverse introduces functions that perform some of the most common operations when working with data frames and uses names for these functions that are relatively easy to remember. For instance, to change the data table by adding a new column, we use mutate. To filter the data table to a subset of rows, we use filter. Finally, to subset the data by selecting specific columns, we use select.

4.3.1 Adding a column with mutate

We want all the necessary information for our analysis to be included in the data table. So the first task is to add the murder rates to our murders data frame. The function mutate takes the data frame as a first argument and the name and values of the variable as a second argument using the convention name=values. So, to add murder rates, we use:

```
library(dslabs)
data(murders)
murders<-mutate(murders, rate= total/population*100000)</pre>
```

Notice that here we used total and population inside the function, which are objects that are not defined in our workspace. But why don't we get an error?

This is one of dplyr's main features. Functions in this packages, such as mutate, know to look for vaiables in the data frame provided in the first argument. In the call to mutate above, total will have the values in murders\$total. This approach makes the code much more readable.

We can see that the new column is added:

head(murders)

```
##
          state abb region population total
                                                   rate
## 1
                      South
                               4779736
                                          135 2.824424
        Alabama
                 AL
## 2
         Alaska
                                           19 2.675186
                 ΑK
                       West
                                 710231
## 3
        Arizona
                 ΑZ
                       West
                               6392017
                                          232 3.629527
       Arkansas
                 AR
                      South
                               2915918
                                           93 3.189390
## 5 California
                 CA
                               37253956
                                         1257 3.374138
                       West
## 6
                 CO
                                           65 1.292453
       Colorado
                               5029196
                       West
```

Although we have overwritten the original murders object, this does not change the object that loaded with data(murders). If we load the murders data again, the original will overwrite our mutated version.

4.3.2 Subsetting with filter

Now suppose that we want to filter the data table to only show the entries for which the murder rate is lower than 0.71. To do this we use the filter function, which takes the data table as the first argument and then the conditional statement as the second. Like mutate, we can use the unquoated variable names from murders inside the function and it will know we mean the columns and not objects in the workspace.

```
filter(murders, rate<=0.71)</pre>
```

```
##
                                region population total
             state abb
                                                               rate
                                                       7 0.5145920
## 1
            Hawaii
                     ΗI
                                  West
                                          1360301
## 2
               Iowa
                     IA North Central
                                          3046355
                                                      21 0.6893484
## 3 New Hampshire
                     NH
                            Northeast
                                          1316470
                                                       5 0.3798036
      North Dakota
                     ND North Central
                                           672591
                                                       4 0.5947151
## 4
## 5
           Vermont
                     VT
                            Northeast
                                           625741
                                                       2 0.3196211
```

4.3.3 Selecting columns with select

Although our data table only has six columns, some data tables include hundreds. If we want to view just a few, we can use the dplyr select function. In the code below we select three columns, assign this to a new object and then filter the new object:

```
new_table<- select(murders, state, region, rate)
filter(new_table, rate<= 0.71)</pre>
```

```
##
             state
                           region
                                        rate
## 1
            Hawaii
                             West 0.5145920
## 2
              Iowa North Central 0.6893484
## 3 New Hampshire
                        Northeast 0.3798036
      North Dakota North Central 0.5947151
## 4
## 5
           Vermont
                        Northeast 0.3196211
```

In the call to select, the first argument murders is an object, but state, region, and rate are variable names.

4.4 Exercises

1. Load the dplyr package and the murders dataset.

```
library(dplyr)
library(dslabs)
data(murders)
```

You can add columns using the dplyr function mutate. This function is aware of the column names and inside the function you can call them unquoted:

```
murders<- mutate(murders, population_in_millions=population/10^6)
```

We can write population rather than murders\$population. The function mutate knows we are grabbing columns from murders. Use the function mutate to add a murders column named rate with the per 100,000 murder rate as in the example code above. Make sure you redefine murders as done in the example code above(murders<- [your code]) so we can keep using this variable.

```
library(dslabs)
data(murders)
murders <- mutate(murders,rate=total/population*100000 )</pre>
```

2. If rank(x) gives you the ranks of x from lowest to highest, rank(-x) gives you the ranks from highest to lowest. Use the function mutate to add a column rank containing the rank, from highest to lowest murder rate. Make sure you redefine murders so we can keep using this variable.

```
murders<-mutate(murders, rank=rank(-rate))</pre>
```

3. With dplyr, we can use select to show only certain columns. For example, with this code we would only show the states and population sizes:

```
select(murders, state, population) %>% head()
```

```
state population
##
## 1
                    4779736
        Alabama
## 2
         Alaska
                     710231
## 3
                    6392017
        Arizona
## 4
       Arkansas
                    2915918
## 5 California
                   37253956
## 6
       Colorado
                    5029196
```

Use select to show the state names and abbreviations in murders. Do not redefine murders, just show the results.

```
select(murders, state, abb) %>% head()
```

```
##
          state abb
## 1
        Alabama AL
## 2
         Alaska AK
## 3
        Arizona
                 ΑZ
## 4
       Arkansas
                 AR.
## 5 California
                 CA
## 6
       Colorado
                 CO
```

4. The dplyr function filter is used to choose specific rows of the data frame to keep. Unlike select which is for columns, filter is for rows. For example, you can show just the New York row like this:

```
filter(murders, state=="New York")
```

```
## state abb region population total rate rank
## 1 New York NY Northeast 19378102 517 2.66796 29
```

You can use other logical vectors to filter rows.

Use filter to show the top 5 states with the highest murder rates. After we add murder rate and rank, do not change the murders dataset, just show the result. Remember that you can filter based on the rank column.

filter(murders, rank<=5)

```
##
                     state abb
                                       region population total
                                                                      rate rank
## 1 District of Columbia
                                                              99 16.452753
                                        South
                                                   601723
                                                                               2
## 2
                 Louisiana
                                        South
                                                  4533372
                                                                  7.742581
                                                            351
                                                                  5.074866
                                                                               4
## 3
                  Maryland
                            MD
                                        South
                                                  5773552
                                                            293
## 4
                  Missouri
                            MO North Central
                                                  5988927
                                                             321
                                                                  5.359892
                                                                               3
## 5
           South Carolina
                                        South
                                                  4625364
                                                             207
                                                                  4.475323
                                                                               5
```

5. We can remove rows using the != operator. For example, to remove Floida, we would do this:

```
no_florida<- filter(murders, state != "Florida")</pre>
```

Create a new data frame called no_south that removes states from the South region. How many states are in this category. You can use the function nrow for this.

```
no_south<- filter(murders, region != "South")
nrow(no_south)</pre>
```

[1] 34

6. We can also use %in% to filter with dplyr. You can therefore see the data from New York and Texas like this:

```
filter(murders, state %in% c("New York", "Texas"))
```

```
##
        state abb
                      region population total
                                                   rate rank
## 1 New York
               NY Northeast
                                19378102
                                            517 2.66796
                                                           29
## 2
               TX
        Texas
                       South
                                25145561
                                            805 3.20136
                                                           16
```

Create a new data frame called murders_nw with only the states from the Northeast and the West. How many states are in this category?

```
murders_nw<-filter(murders, region %in% c("Northeast", "West"))
nrow(murders_nw)</pre>
```

[1] 22

7. Suppose you want to live in the Northeast or West and want the murder rate to be less than 1. We want to see the data for the states satisfying these options. Note that you can use logical operators with filter. Here is an example in which we filter to keep only small states in the Northeast region.

```
filter(murders, population < 50000000 & region =="Northeast")
```

```
##
             state abb
                            region population total
                                                           rate rank
## 1
                                                                   25

                                                                   35
## 5
           Vermont.
                     VT Northeast
                                        625741
                                                    2 0.3196211
                                                                   51
```

Make sure murders has been defined with rate and rank and still has all states. Create a table callsed my_states that contain rows for states satisfying both the conditions: it is in the Northeast or West and the murder rate is less than 1. Use select to show only the state name, the rate, and the rank.

```
my_states<-filter(murders, region %in% c("Northeast","West") & rate <1)
select(my_states, state, rate, rank)</pre>
```

```
##
             state
                         rate rank
## 1

                                 43
```

4.5 The pipe: % > %

With dplyr we can perform a series of operations, for example select and then filter, by sending the results of one function to another using what is called the pipe operator: %>%. Some details are included below.

We wrote code above to show three variables (state, region, rate) for states that have murder rates below 0.71. To do this, we defined the intermediate object new_table. In dplyr we can write code that looks more like a description of what we want to do without intermediate objects:

```
original data -> select -> filter
```

For such an operation, we can use the pipe %>%. The code looks like this:

```
murders %>% select(state, region, rate) %>% filter(rate<=0.71)</pre>
```

```
##
             state
                           region
                                        rate
## 1
            Hawaii
                             West 0.5145920
## 2
              Iowa North Central 0.6893484
## 3 New Hampshire
                        Northeast 0.3798036
## 4
      North Dakota North Central 0.5947151
## 5
           Vermont
                        Northeast 0.3196211
```

This line of code is equivalent to the two lines of code above. What is going on here?

In general, the pipe sends the result of the left side of the pipe to be the first argument of the function on the right side of the pipe. Here is a very simple example:

```
16 %>% sqrt()
```

[1] 4

We can continue to pipe values along:

```
16 %>% sqrt() %>% log2()
```

[1] 2

The above statement is equivalent to log2(sqrt(16)).

Remember that the pipe sends values to the first argument, so we can define other arguments as if the first argument is already defined:

```
16 %>% sqrt() %>% log(base=2)
```

[1] 2

Therefore, when using the pipe with data frames and dplyr, we no longer need to specify the required first argument since the dplyr functions we have described all take the data as the first argument. In the code we wrote:

```
murders %>% select(state, region, rate) %>% filter(rate <= 0.71)
```

```
## state region rate
## 1 Hawaii West 0.5145920
## 2 Iowa North Central 0.6893484
## 3 New Hampshire Northeast 0.3798036
## 4 North Dakota North Central 0.5947151
## 5 Vermont Northeast 0.3196211
```

murders is the first argument of the select function, and the new data frame(formerly new_table) is the first argument of the filter function. Note that the pipe works well with functions where the first argument is the input data. Functions in tidyverse packages like dplyr have this format and can be used easily with the pipe.

4.6 Exercises

1. The pipe %>% can be used to perform operations sequentially without having to define intermediate objects. Start by redefining murder to include rate and rank.

```
murders <- mutate(murders, rate = total / population * 100000, rank = rank(-rate))</pre>
```

In the solution to the previous exercise, we did the following:

```
my_states <- filter(murders, region %in% c("Northeast", "West") & rate <1)
select(my_states, state, rate, rank)</pre>
```

```
##
              state
                          rate rank
## 1
             Hawaii 0.5145920
                                 49
## 2
              Idaho 0.7655102
                                 46
## 3
              Maine 0.8280881
                                 44
## 4 New Hampshire 0.3798036
                                 50
## 5
             Oregon 0.9396843
                                 42
               Utah 0.7959810
## 6
                                 45
## 7
            Vermont 0.3196211
                                 51
## 8
            Wyoming 0.8871131
                                 43
```

The pipe %>% permits us to perform both operations sequentially without having to define an intermediate variable my_states. We therefore could have mutated and selected in the same line like this:

```
mutate(murders, rate = total / population * 100000, rank = rank(-rate)) %>%
select(state, rate, rank)
```

```
##
                       state
                                    rate rank

```

Notice the select no longer has a data frame as the first argument. They first argument is assumed to be the result of the operation conducted right before the %>%.

Repeat the previous exercise, but now instead of creating a new object, show the result and only include the state, rate, and rank columns. Use a pipe %>% to do this in just one line.

```
new_object<-filter(murders, region %in% c("Northeast","West") & rate <1) %>%
select(state, rate, rank)
```

2. Reset murders to the original table by using data(murders). Use a pipe to create a new data frame called my_states that considers only states in the Northeast or West which have a murder rate lower than 1, and contains only the state, rate and rank columns. The pipe should also have four components separated by three %>%. The code should look something like this:

```
#my_states <- murders %>%
  #mutate SOMETHING %>%
  #filter SOMETHING %>%
  #select SOMETHING
```

```
data(murders)
my_states<-murders %>%
  mutate(rate = total / population * 100000, rank = rank(-rate)) %>%
  filter(region %in% c("Northeast","West") & rate <1) %>%
  select(state, rate, rank)
my_states
```

```
